TECHNICAL CONCEPTS REPORT

Customer Churn Intelligence Platform — Code Deep Dive

A comprehensive breakdown of every coding concept, pattern, technique, and library used in the codebase.

Python	Scikit-learn	Pandas/NumPy	XlsxWriter

TABLE OF CONTENTS

1. Project Architecture & File Structure 3
2. Python Language Fundamentals 4
3. Constants, Configuration & Code Organisation 6
4. GUI Programming with Tkinter 7
5. File I/O & Multi-Format Data Loading 8
6. Data Cleaning & Preprocessing (Pandas) 9

10. Feature Engineering 16
11. Customer Segmentation Logic 17
12. KPI Computation & Business Logic 18
13. Excel Report Generation (XlsxWriter) 19
14. Error Handling & Defensive Programming 21
15. Performance Patterns & Optimisation 22
16. Key Coding Patterns Summary 23

1. PROJECT ARCHITECTURE & FILE STRUCTURE

The codebase follows a single-file, sequential script pattern — all logic lives in one Python (.py) file, executed top-to-bottom. This is a common rapid-prototyping architecture.

High-Level Execution Flow

```
1. Import libraries and define constants
2. Launch Tkinter GUI root (hidden)
3. Define all helper functions
4. MAIN block: load file → clean → detect columns → ML → write Excel
5. Error handler (try/except at module level)
```

Logical Layers

Layer	Responsibility
Constants Layer	MAX_RETRIES, SHEET_NAME_LEN, LABEL_ENC_MAX — centralised magic numbers
GUI Layer	Tkinter dialogs: file picker, message boxes, save-as dialog
I/O Layer	load_file() — multi-engine, multi-encoding file reader
Cleaning Layer	Pandas operations: drop_duplicates, dropna, column normalisation
ML Layer	Scikit-learn: imputation, train/test split, Random Forest / GB
Business Logic Layer	Feature engineering, segmentation, KPI computation
Report Layer	XlsxWriter: charts, formats, six-sheet Excel workbook

2. PYTHON LANGUAGE FUNDAMENTALS

2.1 Imports & Standard Library

The script imports from Python's standard library and third-party packages.

Module	Usage in Code
os	File path manipulation: os.path.splitext, os.path.basename, os.path.join
re	Regular expressions for string normalisation and pattern matching
sys	sys.exit(0) — clean programme exit on user cancellation
time	time.strftime() for timestamped filenames; time.sleep() for retry delays
warnings	warnings.filterwarnings('ignore') — suppress sklearn deprecation noise
traceback	traceback.format_exc() — full stack trace for error dialogs

2.2 Functions — Definition, Arguments, Return Values

The code makes heavy use of pure helper functions. Key patterns:

- Default arguments: def MF(bold=False, sz=10, bg=None, ...) — allows partial overrides
- *args (variadic positional): def find_col(df, *keywords) — accepts any number of keywords
- Inner/nested functions: build_report() defines write_table(), add_chart() inside itself for closure access to wb, F, C
- Lambda functions: lambda v, a: F['c_red'] if float(v) > 0.6 else F['c_amber'] — inline conditional format selectors

```
# *args example — variadic keywords
def find_col(df, *keywords):
    cols_norm = {col: norm(col) for col in df.columns}
    for kw in keywords:
        for col, n in cols_norm.items():
            if kw in n: return col
    return None
```

2.3 Data Structures

Structure	Example & Purpose
dict {}	C = {'navy': '#0B1F3A', 'teal': '#007C71', ...} — colour palette lookup
frozenset	YES = frozenset({'yes','y','true','1',...}) — immutable, O(1) membership test
list []	FEATURES = ['tenure','MonthlyCharges',...] — ordered ML feature list
set comprehension	detected = {} — rolling de-duplication of assigned columns
dict comprehension	cols_norm = {col: norm(col) for col in df.columns}
f-strings	f'Rs.{avg_clv:,.0f}' — formatted number embedding in strings

2.4 Conditional Logic

Python ternary expressions are used extensively for compact conditional assignments:

```
# Ternary (conditional expression)
fill = med if (pd.notna(med) and np.isfinite(med)) else float(default_val)

# Walrus (:=) is NOT used here — author favoured traditional assignment

# np.select — vectorised multi-condition assignment (no Python loop needed)
df['Segment'] = np.select(
    [hi_risk & hi_clv, hi_risk & ~hi_clv, ~hi_risk & hi_clv],
    ['High Risk - High Value', 'High Risk - Low Value', 'Low Risk - High Value'],
    default='Low Risk - Low Value'
)
```

2.5 Loops & Iteration

- for … in enumerate(): used in report writing to iterate (index, value) pairs
- for … in zip(): implicit in pandas apply chains
- Nested for loops: encoding × separator matrix in load_file() — tries 6×6 = 36 combinations
- break: exits ML training loop after first successful model fit
- continue: skips failed classifier attempts

```
for Clf, name, kw in [                    # iterate list of (class, name, params)
    (RandomForestClassifier, 'RF', {...}),
    (GradientBoostingClassifier, 'GB', {...}),
]:
    try:
        clf = Clf(**kw)     # **kw unpacks dict as keyword arguments
        clf.fit(Xt, yt)
        break               # stop after first success
    except Exception:
        continue            # try next classifier
```

3. CONSTANTS, CONFIGURATION & CODE ORGANISATION

Using named constants instead of raw numbers ('magic numbers') is a core software engineering principle called the Single Source of Truth (SSOT).

Constant	Purpose
MAX_RETRIES = 3	Number of save-retry attempts before giving up on locked files
SHEET_NAME_LEN = 31	XlsxWriter hard limit on worksheet names — enforced via _trunc()
LABEL_ENC_MAX = 20	Max unique string values before a column is dropped (too many categories)
MIN_ROWS_FOR_ML = 20	Minimum dataset size to attempt ML training

WHY?	Constants make the code maintainable. Changing MAX_RETRIES from 3 to 5 requires editing exactly one line. Magic numbers scattered through code require searching every occurrence.

The _trunc() utility function enforces SHEET_NAME_LEN:

```
def _trunc(s, n=SHEET_NAME_LEN):
    return str(s)[:n]     # slice to max 31 characters
```

4. GUI PROGRAMMING WITH TKINTER

Tkinter is Python's built-in GUI toolkit. The code uses it exclusively for dialogs — no main window is shown to the user.

4.1 Root Window Management

```
root = tk.Tk()            # Create the hidden root window (required by Tkinter)
root.withdraw()           # Hide it — we only want dialogs
root.attributes('-topmost', True)  # Keep dialogs above other windows
```

4.2 The _dlg() Pattern — Temporary Parent Windows

Each dialog creates and immediately destroys a hidden Toplevel window as its parent. This ensures dialogs appear on top and are properly garbage-collected.

```
def _dlg():
    w = tk.Toplevel(root)  # child window of root
    w.withdraw()           # keep it invisible
    w.attributes('-topmost', True)
    return w

def info(title, msg):
    w = _dlg()
    messagebox.showinfo(title, msg, parent=w)
    w.destroy()            # clean up
```

4.3 Dialog Types

Function	Purpose
messagebox.showinfo()	Informational popup with OK button
messagebox.showwarning()	Warning popup with yellow icon
messagebox.showerror()	Error popup with red X icon
messagebox.askyesno()	Returns True/False — used for Yes/No decisions
filedialog.askopenfilename()	Native OS file-picker — returns selected path
filedialog.asksaveasfilename()	Native OS save dialog — returns destination path

4.4 File Dialog with Type Filters

```
p = filedialog.askopenfilename(
    parent=w,
    title='Select Your Dataset',
    filetypes=[
        ('All Supported Files', '*.csv *.xlsx *.xls *.ods *.txt *.tsv'),
        ('CSV Files', '*.csv'),
        ('Excel Files', '*.xlsx *.xls *.xlsm *.xlsb'),
    ],
)
```

5. FILE I/O & MULTI-FORMAT DATA LOADING

5.1 Multi-Engine File Loading Strategy

load_file() implements a defensive cascade: try every combination of engine, encoding, and separator until one succeeds or all fail.

CONCEPT	This is a Retry / Fallback Chain pattern — extremely useful when dealing with real-world data files that may be malformed, use non-standard encodings, or come from different regions.

5.2 CSV Loading — Encoding × Separator Matrix

```
ENCODINGS  = ('utf-8-sig', 'utf-8', 'latin1', 'cp1252', 'iso-8859-1', 'utf-16')
SEPARATORS = (None, ',', ';', '\t', '|', ':')

for enc in ENCODINGS:
    for sep in SEPARATORS:    # 6 × 6 = 36 combinations tried
        df = _try_csv(path, enc, sep)
        if df is not None: return df
```

5.3 Excel Loading — Multiple Engines

Engine	File Type
openpyxl	Default engine for .xlsx, .xlsm, .xlsb files
xlrd	Legacy engine for .xls (old binary format)
odf	Open Document Format engine for .ods files
None	Pandas auto-selects engine (final fallback)

5.4 ExcelFile.sheet_names — Multi-Sheet Handling

```
xl = pd.ExcelFile(path, engine=eng)
for sheet in xl.sheet_names:   # iterate every sheet
    df = xl.parse(sheet, dtype=str)  # read all values as strings first
    df = df.dropna(how='all').dropna(axis=1, how='all')
    if len(df) >= 1 and len(df.columns) >= 2:
        return df  # return first usable sheet
```

6. DATA CLEANING & PREPROCESSING (PANDAS)

6.1 Core DataFrame Operations

Operation	Purpose
df.dropna(how='all')	Remove rows where every column is NaN
df.dropna(axis=1, how='all')	Remove columns where every value is NaN
df.drop_duplicates()	Remove identical rows
df.reset_index(drop=True)	Re-number rows 0, 1, 2, … after filtering
df.columns.str.match(r'^Unnamed')	Regex match to drop auto-generated Pandas columns
df.select_dtypes(include='object')	Filter to only string/text columns
df.select_dtypes(include=np.number)	Filter to only numeric columns

6.2 clean_num() — The Currency Converter

This function handles real-world numeric columns that may contain currency symbols, thousand-separators, or European decimal formats.

```
def clean_num(series):
    s = (series.astype(str)
              .str.strip()                        # remove whitespace
              .str.replace(r'[₹$€£¥]', '', regex=True)  # strip symbols
              .str.replace(r'\s+', '', regex=True))       # remove spaces
    # _fix() handles 3 locale formats:
    # European: 1.234,56 → 1234.56
    # US:       1,234.56 → 1234.56
    # Indian:   1,23,456 → 123456
    s = s.apply(_fix)
    return pd.to_numeric(s, errors='coerce')  # non-parseable → NaN
```

6.3 The 40% Conversion Threshold

```
temp = clean_num(df[col])
if temp.notna().sum() / max(len(temp), 1) >= 0.40:
    df[col] = temp  # only convert if ≥40% of values parsed successfully
# This prevents converting a text column just because it has a few numbers
```

6.4 Label Encoding Categorical Columns

String columns with 2–20 unique values are converted to integers using LabelEncoder. Columns with 0–1 or 21+ unique values are dropped (set to NaN).

```
le = LabelEncoder()
# fit_transform assigns an integer to each unique string:
# ['No','Yes','No'] → [0, 1, 0]
df[col] = le.fit_transform(
    df[col].fillna('__missing__').astype(str)  # fill NaN before encoding
)
```

6.5 Imputation — Filling Missing Values

```
imputer = SimpleImputer(strategy='median')
# Replaces NaN with the median of that column
# Median is preferred over mean — robust to outliers
X = pd.DataFrame(imputer.fit_transform(X_raw), columns=FEATURES)
```

6.6 Safe Column Binning — safe_cut()

pd.cut() is used to create histogram buckets. It fails on constant series (all values identical), so safe_cut() wraps it in a try/except with a graceful fallback.

```
cuts = pd.cut(s, bins=min(bins, s.nunique()), duplicates='drop')
# duplicates='drop' prevents errors when bins have identical edges
# nunique() ensures we never ask for more bins than unique values
```

7. REGEX & STRING MANIPULATION

Regular expressions (regex) appear throughout the codebase for column normalisation, data cleaning, and format detection.

7.1 norm() — Column Name Normaliser

```
def norm(s):
    # [^a-z0-9] matches any character that is NOT a-z or 0-9
    # re.sub replaces all such characters with ''
    return re.sub(r'[^a-z0-9]', '', str(s).lower())

# Examples:
# 'Monthly Charges' → 'monthlycharges'
# 'Customer_ID (No.)' → 'customeridno'
```

7.2 Regex Patterns Used in clean_num()

Pattern	Matches / Purpose
\d{1,3}(\.\d{3})+(,\d+)?	European format: 1.234,56 — dot as thousand, comma as decimal
\d,\d{3}[.,]	US format: 1,234. — comma as thousand separator
\d,\d{2},\d{3}	Indian format: 1,23,456
[₹$€£¥]	Currency symbols — stripped before parsing
[^\d.\-]	Any non-numeric character after locale fix — removed
\s+	One or more whitespace characters — removed

7.3 re.fullmatch() vs re.search()

```
re.fullmatch(r'\d{1,3}(\.\d{3})+(,\d+)?', v)
# fullmatch: ENTIRE string must match the pattern

re.search(r'\d,\d{3}[.,]', v)
# search: pattern can appear ANYWHERE in the string
```

7.4 Column Name Matching with norm()

```
# find_col uses norm() to enable fuzzy column matching:
# 'Monthly Charges', 'monthly_charges', 'MonthlyCharges'
# all normalise to 'monthlycharges' — found by keyword 'monthlycharge'

for kw in keywords:                    # check keywords in priority order
    for col, n in cols_norm.items():
        if kw in n: return col         # 'in' = substring check
```

8. NUMERICAL COMPUTING (NUMPY)

8.1 Vectorised Operations

NumPy operations work on entire arrays at once — no Python loops needed. This is orders of magnitude faster than iterating row-by-row.

```
# Vectorised boolean masking — no loop:
hi_risk = df['Churn_Prob'] >= 0.60  # returns boolean Series
hi_clv  = df['Predicted_CLV'] >= df['Predicted_CLV'].median()

# Vectorised arithmetic:
df['AvgMonthlySpend'] = (df['TotalCharges'] / (df['tenure'] + 1)).clip(lower=0)

# np.log1p(x) = log(x + 1) — handles x=0 safely, log(0) = -inf
df['ValueScore'] = np.log1p(df['TotalCharges'])
```

8.2 np.select() — Multi-Condition Assignment

np.select() is the vectorised equivalent of a chain of if/elif/else conditions applied to every row simultaneously.

```
df['Segment'] = np.select(
    condlist=[hi_risk & hi_clv,          # condition 1
              hi_risk & ~hi_clv,          # condition 2
              ~hi_risk & hi_clv],         # condition 3
    choicelist=['High Risk - High Value',
                'High Risk - Low Value',
                'Low Risk - High Value'],
    default='Low Risk - Low Value'        # else branch
)
```

8.3 np.where() — Binary Vectorised Conditional

```
# np.where(condition, value_if_true, value_if_false)
df['Churn'] = np.where(
    df['tenure'] < df['tenure'].median(),
    1,    # churned
    0     # retained
).astype(int)
```

8.4 Key NumPy Functions

Function	Purpose
np.isfinite(v)	Returns False for NaN, +inf, -inf — used in safe_float() guard
np.log1p(x)	log(x+1) — safe logarithm that handles zero values
np.select()	Vectorised multi-condition choice (see above)
np.where()	Vectorised binary conditional
np.number	dtype specifier — selects all numeric columns in select_dtypes()
.clip(lower=0)	Clamp all values to minimum 0 — prevents negative charges/CLV
.rank(pct=True)	Rank values as percentiles (0.0 to 1.0) — used in risk scoring

9. MACHINE LEARNING PIPELINE (SCIKIT-LEARN)

9.1 The ML Pipeline Steps

Step	Implementation
1. Imputation	SimpleImputer(strategy='median') — fill NaN with column medians
2. Feature Matrix	X = processed DataFrame of 7 engineered features
3. Target Vector	y = df['Churn'] — binary 0/1 labels
4. Train/Test Split	train_test_split(X, y, test_size=0.20, stratify=y)
5. Model Training	clf.fit(Xt, yt) — Random Forest or Gradient Boosting
6. Evaluation	accuracy_score, roc_auc_score on held-out test set
7. Prediction	clf.predict_proba(X)[:,1] — probability of class 1 (Churned)

9.2 Train/Test Split

```
Xt, Xe, yt, ye = train_test_split(
    X, y,
    test_size=0.20,      # 20% for evaluation, 80% for training
    random_state=42,     # fixed seed → reproducible results
    stratify=y           # keep class balance in both splits
)
# X_t = training features, X_e = evaluation features
# y_t = training labels,   y_e = evaluation labels
```

9.3 Random Forest Classifier

An ensemble of decision trees. Each tree is trained on a random sample of data and features. Final prediction is the majority vote (classification) or average (probability).

```
RandomForestClassifier(
    n_estimators=300,          # number of decision trees
    max_depth=12,              # max depth per tree (prevents overfitting)
    class_weight='balanced',   # adjust for imbalanced churn datasets
    random_state=42,           # reproducibility
    n_jobs=-1                  # use ALL CPU cores
)
```

9.4 Gradient Boosting Classifier — Fallback

Trains trees sequentially; each tree corrects errors of the previous one. Usually more accurate but slower to train. Used if Random Forest fails.

```
GradientBoostingClassifier(
    n_estimators=150,    # fewer trees than RF because sequential = slower
    max_depth=5,
    random_state=42
)
```

9.5 Model Evaluation Metrics

Metric / Parameter	Explanation
Accuracy	% of predictions that are correct. Misleading on imbalanced data.
AUC-ROC	Area Under the ROC Curve. 1.0 = perfect, 0.5 = random. Better than accuracy for churn.
predict_proba()	Returns probability [P(class=0), P(class=1)] — we use [:,1] for churn probability
class_weight='balanced'	Automatically adjusts for datasets with more non-churners than churners

9.6 Synthetic Labels — When ML Cannot Be Trusted

KEY INSIGHT	If no real churn column exists, the code generates synthetic labels using a risk-score formula. ML is still trained, but accuracy/AUC are suppressed — reporting them would be meaningless as the model is merely learning its own formula.

10. FEATURE ENGINEERING

Feature engineering transforms raw data into derived columns that capture business meaning — making ML models more predictive.

Feature	Formula & Business Meaning
AvgMonthlySpend	TotalCharges / (tenure + 1) — average spend per month of relationship
ValueScore	log1p(TotalCharges) — log-transforms to reduce skew from outliers
LoyaltyScore	tenure × (TotalCharges / (MonthlyCharges + 1)) — reward long, high-spend customers
SpendVariance	|(MonthlyCharges − AvgMonthlySpend)| / (AvgMonthlySpend + 1) — detects spending changes

Why +1 in denominators?

```
df['AvgMonthlySpend'] = TotalCharges / (tenure + 1)
# +1 prevents division by zero when tenure = 0 (brand new customer)
# This is called 'Laplace smoothing' or 'additive smoothing'
```

Synthetic Risk Score Formula

```
risk_score = (
    df['tenure'].rank(pct=True).rsub(1) * 0.40   # short tenure → high risk
  + df['MonthlyCharges'].rank(pct=True)  * 0.30  # high charges → high risk
  + spend_variance.rank(pct=True)        * 0.20  # volatile spend → high risk
  + df['TotalCharges'].rank(pct=True).rsub(1) * 0.10  # low total → high risk
)
# .rsub(1) = 1 - series (inverts the ranking: rank 1.0 becomes 0.0)
# Customers above 65th percentile are labelled Churned
```

11. CUSTOMER SEGMENTATION LOGIC

The 2×2 Risk × Value matrix is a classic business framework (similar to the BCG matrix). It creates four customer buckets for targeting.

Segment	Action
High Risk – High Value	Churn_Prob ≥ 0.60 AND Predicted_CLV ≥ median → Immediate retention action!
High Risk – Low Value	Churn_Prob ≥ 0.60 AND Predicted_CLV < median → Let go or low-cost save
Low Risk – High Value	Churn_Prob < 0.60 AND Predicted_CLV ≥ median → Protect and delight
Low Risk – Low Value	Churn_Prob < 0.60 AND Predicted_CLV < median → Monitor, no urgency

Risk Tier — pd.cut()

```
df['Risk_Tier'] = pd.cut(
    df['Churn_Prob'],
    bins=[0, 0.30, 0.60, 1.001],           # bin edges
    labels=['Low Risk (0-30%)',
            'Medium Risk (30-60%)',
            'High Risk (60-100%)'],
    include_lowest=True                    # include 0.0 in first bin
)
```

12. KPI COMPUTATION & BUSINESS LOGIC

12.1 Core KPIs

KPI	Computation
churn_rate	df['Churn'].mean() × 100 — % of customers who churned
retention_rate	100 − churn_rate — clamped to [0, 100]
avg_clv	df['Predicted_CLV'].mean() — average predicted customer value
revenue_at_risk	Sum of (MonthlyCharges × 12) for Churn_Prob ≥ 0.60 customers
total_clv	df['Predicted_CLV'].sum() — total portfolio value
high_risk_pct	high_risk_n / total_cust × 100

12.2 safe_float() — Defensive Number Guard

```
def safe_float(v, default=0.0):
    try:
        f = float(v)
        return f if np.isfinite(f) else default  # guard against inf
    except Exception:
        return default  # guard against NaN, None, strings

# Used everywhere KPIs are computed — prevents NaN/inf in report cells
churn_rate = round(safe_float(df['Churn'].mean()) * 100, 2)
```

12.3 CLV Formula

FORMULA	Predicted_CLV = TotalCharges × (1 − Churn_Prob). This is a retention-weighted historical proxy — NOT a DCF (Discounted Cash Flow) model. It represents the portion of past spend expected to be retained.

12.4 Logical Inconsistency Repair

```
# TotalCharges cannot logically be less than MonthlyCharges
bad_total = df['TotalCharges'] < df['MonthlyCharges']
df.loc[bad_total, 'TotalCharges'] = (
    df.loc[bad_total, 'tenure'] * df.loc[bad_total, 'MonthlyCharges']
)
# df.loc[mask, col] = value — boolean-indexed assignment
# Repairs corrupted data rather than dropping rows
```

13. EXCEL REPORT GENERATION (XLSXWRITER)

13.1 ExcelWriter Context Manager

```
with pd.ExcelWriter(out_path, engine='xlsxwriter') as writer:
    wb = writer.book  # access the underlying XlsxWriter Workbook
    # ... write all sheets ...
# File is automatically closed and saved when 'with' block exits
# This is the Context Manager pattern (using __enter__/__exit__)
```

13.2 Format Factory — MF()

Instead of creating dozens of named format objects, MF() is a factory function that creates XlsxWriter format objects from parameters. This follows the Factory Method pattern.

```
def MF(bold=False, sz=10, fc='#0B1F3A', bg=None, num_fmt=None, ...):
    d = {'font_name': 'Calibri', 'font_size': sz, 'bold': bold, ...}
    if bg:      d['bg_color']   = bg
    if num_fmt: d['num_format'] = num_fmt
    return wb.add_format(d)  # returns XlsxWriter format object
```

13.3 Alternating Row Colours (Striped Table)

```
for ri in range(len(df_t)):
    alt = (ri % 2 == 1)  # True for odd rows (0-indexed)
    fmt = F['cell_alt' if alt else 'cell']  # alternate white/grey
    ws.write(row, col, value, fmt)
```

13.4 Chart Creation

Chart Element	Usage
column chart	Vertical bars — used for segment counts, probability distribution
bar chart	Horizontal bars — used for CLV distribution
doughnut chart	Ring chart — used for Risk Tier breakdown
data_labels	Value annotations on bars — bold, 9pt, navy
set_plotarea()	Light grey background (#F0F4F8) behind chart data
insert_chart()	Places chart at a specific cell in the worksheet

13.5 Conditional Format Functions

Format functions are lambdas that receive the cell value and return the appropriate format object. Used for colour-coded Churn Rate in Segment Summary:

```
def cr_fmt(val, alt):
    v = float(val)
    if v > 0.6:  return F['c_red']    # red background for >60%
    if v > 0.3:  return F['c_amber']  # amber for 30-60%
    return F['c_green']               # green for <30%
```

13.6 Merge Cells & Freeze Panes

```
ws.merge_range(1, 0, 1, TITLE_LAST_COL, 'TITLE TEXT', F['title'])
# merge_range(row1, col1, row2, col2, data, format)

ws.autofilter(0, 0, len(df), len(df.columns) - 1)  # enable column filters
ws.freeze_panes(1, 0)  # keep header row visible when scrolling
```

14. ERROR HANDLING & DEFENSIVE PROGRAMMING

14.1 Top-Level try/except Wrapper

```
try:
    # entire main logic block
except SystemExit:
    pass  # user cancelled — clean exit, no error shown
except Exception as e:
    tb = traceback.format_exc()
    err('Unexpected Error', f'{str(e)}\n\nTraceback:{tb[-1200:]}') # show dialog
finally:
    root.destroy()  # always close Tkinter, even after errors
```

14.2 The safe_write_excel() Retry Loop

Handles the common scenario where the output file is open in Excel (PermissionError). Offers auto-rename or manual re-save without crashing.

```
for attempt in range(1, MAX_RETRIES + 1):
    try:
        writer_fn(attempt_path)  # try to write
        return attempt_path      # success
    except PermissionError:
        # offer auto-rename (timestamp) or manual new location
        ...
    except OSError as exc:
        if attempt == MAX_RETRIES: raise  # give up after 3 tries
        time.sleep(0.5)  # brief pause before retry
```

14.3 Defensive Fallbacks Throughout

Pattern	Guarded Against
max(len(df), 1)	Prevents division by zero when DataFrame is empty
pd.notna(med) and np.isfinite(med)	Guards against NaN median from all-NaN column
series.fillna(0).clip(lower=0)	Ensures no negative values enter calculations
except Exception: continue	ML training — silently try next model on failure
or ''	p or '' — converts None (cancelled dialog) to empty string
list(dict.fromkeys(e))[:3]	De-duplicate error messages before showing in dialog

15. PERFORMANCE PATTERNS & OPTIMISATION

Pattern	Performance Benefit
Vectorisation over loops	All data processing uses Pandas/NumPy operations — no row-by-row Python loops
n_jobs=-1	RandomForest uses all CPU cores in parallel
sample=500 in auto_col_widths	Column width calculation samples 500 rows max — avoids O(n) scan on huge files
frozenset for membership	frozenset({...}) — O(1) lookup vs O(n) for list
break after first ML model	Only trains one model — stops immediately on success
dict comprehension	cols_norm = {col: norm(col) ...} — normalise once, reuse many times
warnings.filterwarnings	Suppresses sklearn warnings that would slow output
copy() for original_df	raw_df.copy() prevents modifications to original — avoids reloading

16. KEY CODING PATTERNS SUMMARY

Pattern	Where Used	Benefit
Factory Method	`MF() format factory`	One function, hundreds of format variants
Fallback Chain	`load_file() engine cascade`	Robust to real-world file variety
Retry Loop	`safe_write_excel()`	Handles locked files gracefully
Closure	`Inner functions in build_report`	Access wb, F, C without globals
Strategy Pattern	`RF then GB classifier list`	Swap algorithms without changing logic
SSOT Constants	`MAX_RETRIES, LABEL_ENC_MAX`	Single edit point for tunable values
Boolean Masking	`hi_risk & hi_clv segments`	Vectorised multi-condition filtering
Defensive Guard	`safe_float(), max(len,1)`	Zero-crash on bad/empty data
Columnar Normalise	`norm() for column matching`	Flexible, locale-agnostic detection
Synthetic Fallback	`Risk score when no churn col`	Always produces useful output
